Key words: Rabbit, Tongue, Papillae, Light and Scanning Microscope

ABSTRACT

The distribution and structure of the lingual papillae on rabbit tongue were studied in relation to its feeding habits by means of light and scanning electron microscopy. The tongue of rabbit is of about 5 cm in length and 9 mm in width. The dorsal surface of the tongue is differentiated into four regions according to the nature of papillae; apex, body, lingual torus (intermolar prominence) and root. On the surface of the apex and body of the tongue there are four main types of papillae: filiform, fungiform, vallate and foliate papillae. The filiform one can be differentiated morphologically into five sub types of variable size and shape according to their location. Fungiform papillae are numerous on the anterior part of the tongue. They are elliptical or circular in shape and embedded in between filiform ones. In this region both filiform and fungiform are devoid of taste buds indicating their mechanoreceptive function. Two oval vallate papillae with numerous taste buds are situated on the side wall of the tongue root, elucidating their chemoreceptive role. A Pair of patches having well developed foliate papillae is observed in the latero-posterior part of the tongue. Each is oval in shape and has several parallel papillae lacking taste buds and may separate by shallow grooves. Histological observation indicates keratinization of the dorsal surface of the tongue with variable degrees.

INTRODUCTION

The fact that rabbit has adapted to herbivorous diet with modified teeth (Davis, 1964) suggested that the tongue might also exhibit modifications related to its specialized diet. In primates, some carnivorous and rodents, the tongue has lost its importance in the function of food prehension, since these animals use their paws to bring food to the mouth (Iwasaki, 2002). The feeding mechanism is clearly an important factor that determines the success of vertebrates tongue to the environment (Roth and Wake, 1989).

Early studies on the morphology of the tongue surface carried by Sonntag (1923) described the shape, situation and types of lingual papillae in different mammalian species. Later on, there are numerous studies of the tongue papillae by means of SEM in rat (Iida *et al.*, 1985), cat (Chamorro *et al.*, 1987), horse and cow (Paz *et al.*, 1988), dog (Holland *et al.*, 1989), and monkey (Iwasaki *et al.*, 1992). It was found that the surface of the mammalian tongue has a papillary system with two specific functions: gustatory and mechanical. The gustatory papillae show taste buds and pores, whereas the mechanical papillae play a role in tongue surface protection, food prehension mastication and swallowing (Chamorro *et al.*, 1994)

Some what recently, (Emura *et al.* 2000 a&b and Emura *et al.* 2004) studied the morphology of the lingual surface in carnivores with the scanning electron microscope. The general description of the lingual papillae made by koeing and Liebig (2001) revealed different variations in morphology and distribution of papillae on dorsal lingual surface among different animal species.

The present study was performed to investigate the histological and morphological differences of the tongue papillae in the domestic rabbits, *Oryctolagus cuniculus*, and their relation to food item in comparison with other animals using scanning and light microscopes.

Materials and Methods

The observations were conducted on eight tongues of adult rabbit of both sexes. The tongues were dissected from the mandible, fixed in 10% neutral formaldehyde, and routinely prepared for observation under a scanning electron microscope. The samples of the tongue were dehydrated in a series of ethanol (70–99.8%) and acetone, then subsequently dried at the critical point using CO₂ (Critical Point Dryer K850, Emitech). The specimens were carefully mounted on aluminum stages with double-sided carbon tape, sputtered with 15 nm thick gold coat (Sputter Coater S 150B, Edwards) and investigated under the Scanning Electron Microscope JEOL (JSM-5400 LV) in Regional Centre of Mycology and Biotechnology, Al-Azhar University, Cairo, Egypt.

Other dissected tongue specimens were fixed in 10% neutral buffered formalin and routinely prepared as usual for normal histological examinations under light microscope.

RESULTS

Anatomically, the tongue of the rabbit is of about 45-50 mm long and 8-9 mm width. Three regions are distinguished in the dorsal surface of the tongue: the apex (A), the body of the tongue (B) with a well-developed intermolar prominence (P) and root (R) as showed in figure (1). The tip of the tongue is

convex and covered with condensed filiform and randomly scattered fungiform papillae (Fig. 2).

The intermolar prominence which is observed in the middle region and called torus lingual or intermolar prominence is covered with special type of filiform papillae (Fig. 3).

By SEM several types of papillae can be seen and designated as filiform, fungiform, foliate and vallate papillae (Figs. 2, 3& 4) in the different regions of the dorsal surface of rabbit tongue.

Filiform papillae occupied the entire dorsal surface and continued to the lateral borders; their size and shape, however varied according to the location. In the torus lingual, filiform papillae looked like a hand with primary papillae and other secondary ones growing from the tip of the primary papillae (Figs. 5, 6). The secondary papillae differ in number ranging between three and five. Near the tongue root on the lateral border of the prominence, pawn chess like filiform papillae with vertical orientation are dispersed (Figs. 7, 8). Tapering filiform papilla with broad base and pending distal ends are seen on the periphery of the intermolar prominence (Figs. 9, 10). Saw shaped filiform papillae with sharp pointed ends cover almost of the dorsal surface of the prominence; these are relatively tighter and taller than the papillae on the anterior part (Figs. 11, 12). Cone shaped filiform papillae caudally pended with concave anterior surface are seen scattered on the tongue root (Figs. 13, 14).

Fungiform papillae are present in the anterior region of the tongue. They were elliptical or circular in shape and embedded in between filiform papillae (Fig. 15). At higher magnification, it is possible to observe dermal papilla contoured by the polygonal cells and keratinized epithelium (Fig. 16).

In the posterior region of the tongue there is a pair of patches loaded with circular vallate papillae, with several taste pores deep depression

inbetween (Fig. 17). In addition numerous taste buds are seen on the side wall of the vallate papilla in-between the slightly keratinized epithelia stratified (Fig. 18).

A pair of well-developed foliate papillae are found in the latero-posterior portion of the tongue, each was oval in shape and had several parallel projections (ridges) separated by shallow grooves and devoid of taste buds and covered by keratinized layer (Figs. 19, 20).

Discussion

The lingual prominence of the rabbit, present in the caudal area of the tongue, is a characteristic structure of the most grass-eating artiodactyls, including cattle, sheep and goats (**Tadjali and Pazhoomand, 2004**), but is lacking in carnivores and in omnivorous animals such as pigs (**Zheng and Kobayashi, 2006**).

The filiform papillae are the main mechanical papillae of the rabbit. Each consists of one large main process and several slender accessory processes. These conical papillae participate in transporting and swallowing of food (**Adnyane et al., 2011**). The filiform papillae in the rabbit are caudally directed, as were those reported in hedgehog by **Nasr (2012)** and rat by **Nasr et al. (2012)**. So, it can be believed that the presence and distribution of filiform papillae is almost the same in different mammals. However, SEM examination revealed that the filiform papillae of rabbit presented wide morphological variations between different localizations on the tongue surface. This morphological variability together with the direction of bending lead to the assumption that the filiform

papillae are involved in directing and facilitating the process of mastication and swallowing of food which was also reported by **Son et al. (2000)**. They suggested that, the bending of filiform papillae toward opposite direction aimed to hold the food until it was swallowed.

Otherwise the fungiform papillae are the most numerous gustatory papillae on the tongue of animals, and their distribution on the apex and body of the tongue is characteristic not only for the rabbit, but also for other animal species (**Kulawik and Godynicki, 2007**). In the rabbit of the present study the fungiform papillae are more densely distributed among the filiform papillae at the dorsal surface of the tip than the body and the root of the tongue. They were elliptical or circular in shape and are separated from the filiform papillae by a shallow groove, which is similar to the configuration reported in the lamb (**Tadjali and Pazhoomand, 2004**) and goat (**Kurtul and Atalgin, 2008**). As in other species of mammals, **Jackowiak (2006)** suggested a protective function for filiform papillae surrounding the fungiform ones. Similar observations were also reported by (**Kobayashi et al., 1992**) in *Tupais glis*.

The present study showed the absence of taste buds in the fungiform papillae of the rabbit as reported also in the Reeves' muntjac deer (**Zheng and Kobayashi, 2006**). Whereas, no taste buds are found in the fungiform papillae of the donkey (**Mahmoud et al., 2002**), the Egyptian camel (**Korany and Bachir, 2004**) goat (**Kurtul and Atalgin, 2008**), hedgehog (**Nasr, 2012**) and rat (**Nasr et al., 2012**). Furthermore, the presence of the thick stratified highly keratinized covering layers on the fungiform papillae may give support and protect the lingual papillae against the strong mechanical stress exerted during chewing of rigid food (**Mahmoud et al., 2002**). This feature is similar to that observed in papillae of the barking deer (**Adnyane et al., 2011**).

The vallate papillae were the largest lingual papillae in the rabbit. Each of these papillae was surrounded by a continuous deep groove. Their surface

was covered by stratified squamous less keratinized epithelial cells. The taste buds in the vallate papillae of rabbit were numerous and concentrated in the side walls of the papillae, close to the papillary groove. This feature is similar to the configuration observed in Reeves' muntjac deer (**Zheng and Kobayashi, 2006**).

The present observations confirmed the characteristics of the foliate papillae reported by (**Watanabe et al., 1988**) and (**Kobayashi, 1992**), which presented some parallel projections (ridges) separated by grooves .
